Submitted for publication: July 2002
Accepted for publication: May 2003
Key words: Non-Saccharomyces, yeasts, wine, fermentation

The role of non-Saccharomyces yeasts in wine production has been extensively debated and there is growing evidence that non-Saccharomyces yeasts play an important role in wine quality. It has been suggested that metabolites formed by some non-Saccharomyces species may contribute to wine quality. Recently a comprehensive, long-term research programme was launched by role players in the South African wine industry, whose aims include the isolation, characterisation and preservation of the natural yeast biodiversity of the Western Cape. As part of the programme, this paper investigates the presence of non-Saccharomyces yeast species over three vintages in four vineyards and musts in four distinct areas of the Western Cape. Samples were taken and the non-Saccharomyces yeast isolates were characterised by biochemical profiling and pulse field gel electrophoresis. In total 720 yeasts representing 24 species were isolated. Predominant species found in the must samples, i.e. Candida stellata, Kloeckera apiculata, Candida pulcherrima and Candida colliculosa, should have the most impact on subsequent fermentation.

The role of non-Saccharomyces yeasts in wine production has been debated extensively. Earlier schools of thought referred to non-Saccharomyces yeasts as primarily spoilage organisms (Amerine & Cruess, 1960; Van Zyl & Du Plessis, 1961; Rankine, 1972; Le Roux et al., 1973). It was further accepted that they died during the initial stages of fermentation due to the toxicity of the rising alcohol concentration from the metabolism of Saccharomyces cerevisiae. Consequently, they were seen to be of little significance in wine production. Recently, the work of Fleet et al. (1984), Heard & Fleet (1985), Longo et al. (1991), Todd (1995) and Gafner et al. (1996) showed that non-Saccharomyces yeasts survived during fermentation and could reach cell concentrations of $10^6$ to $10^8$ cells/mL. These numbers are similar to those reached by S. cerevisiae.

It has been suggested that metabolites formed by some non-Saccharomyces species may contribute to wine quality (Fleet et al., 1984; Gil et al., 1996; Lema et al., 1996; Soden et al., 2000). An example is glycerol production by Candida stellata (Ferraro et al., 2000) and ester production by Candida pulcherrima (Bisson & Kunkee, 1991) that in some wines can have a positive influence on wine quality. Other species, such as Kloeckera apiculata, are associated with acidic acid production that can be detrimental to wine quality. However, large strain variability can be found among non-Saccharomyces species and not all strains within a particular species form high levels of oenologically negative compounds (Romano et al., 1992; Romano & Suzzi, 1993). Some non-Saccharomyces species also possess P-glycosidase activity that can hydrolyse glycosically-bound aroma precursors (Todd, 1995). This supports the belief of winemakers, in especially the Old World wine regions, that indigenous yeasts impart a distinct regional and desired characteristic to their wines (Jackson, 1994).

The main sources of indigenous yeast flora in the must are the grapes and the equipment used to process the grapes (Peynaud & Domercq, 1959; Rosini, 1984; Lonvaud-Funel, 1996). Non-Saccharomyces yeasts are the dominant species on the grapes, but are found in lesser numbers in the cellar and on the cellar equipment (Vaughan-Martini & Martini, 1995; Boulton et al., 1996; Constanti et al., 1997). At crushing, these yeasts can be introduced into the must.

The specific environmental conditions in the must, i.e. high osmotic pressure, the presence of SO2, the temperature and cellar hygiene, all play a role in determining which species can survive and grow in the must (Longo et al., 1991). However, in order to exploits the potential benefits and to minimise potential spoilage by undesired non-Saccharomyces yeasts, the oenologically important yeast populations on grapes and in must, as well as the effect of winemaking practices on these yeasts, should be known.

*This work was partially presented as a paper at the 23rd SASEV Congress, 18-19 November 1999, Somerset West and as a poster at the 2nd International SASEV Congress, 8-10 November 2000, Cape Town.

This knowledge will help realise the predictions of Heard (1999) concerning the use of mixed yeast starter cultures tailored to reflect the characteristics of a given wine region.

The composition of vineyard and wine microflora in South Africa received attention in earlier work done by Du Plessis (1959), Van Zyl & Du Plessis (1961) and Van Kerken (1963); however, it is unclear if any of these isolates have survived to the present. Recently, the distribution of indigenous S. cerevisiae yeasts in vineyards in the cooler, coastal and the warmer, inland regions of South Africa has been covered extensively by Van der Westhuizen et al. (2000a, 2000b) and Khan et al. (2000), respectively. These studies formed part of a comprehensive and ongoing long-term, collaborative research programme by ARC Infruitec-Nietvoorbij and Stellenbosch University. The programme’s nine objectives were detailed by Pretorius et al. (1999). They include the isolation, characterisation and preservation of natural yeast biodiversity from the 350-year-old wine-producing regions of the Western Cape of South Africa; an investigation into the occurrence of area-specific indigenous yeasts and winery yeasts that impart a distinctive characteristic to wines from that area; and the evaluation of yeast isolates for continuous wine yeast selection and strain development programmes which have the ultimate aim of providing an appropriate yeast per cultivar, per area, per wine type. While the aforementioned is a daunting task, this study is the first to concentrate on the non-Saccharomyces group of yeasts. The aim of this study, as part of the above-mentioned programme, was to obtain an oenologically biased collection of non-Saccharomyces yeasts that could be used in future selection programmes for use in wine production. Concurrently, a broad overview of some of the non-Saccharomyces yeast species predominantly found in commercial vineyards and grape musts of the Western Cape, South Africa, could be obtained.

MATERIALS AND METHODS

Areas sampled

One Chardonnay vineyard and accompanying commercial cellar in each of four production areas was selected for sampling in three vintages, i.e. 1997, 1998 and 2000. The four vineyards and their respective cellars were in Constantia (cooler temperature zone), Stellenbosch and Stanghoek (intermediate temperature zone) and Robertson (warmer zone) (Fig. 1). These four areas were selected according to the climate classification of Le Roux (1974), as adapted by De Villiers (1997).

Sample collection and yeast isolation

Whole bunches of healthy Chardonnay grapes (1-2 kg per sampling point) were aseptically gathered over the whole vineyard from 10-15 vines (both the shaded and unshaded sides) the day before commercial harvesting, dropped directly into sterile plastic bags and transported to the laboratory in cool bags. At the laboratory the grapes were crushed by hand in the sealed bags. After thorough shaking, the bags were opened and the juice (500 mL) was poured into a sterile closed beaker and mixed (full speed on magnetic stirrer for 1 min). One mL of juice was taken and a dilution series made in sterile NaCl (0.85%) solution and plated onto YPD agar (1% yeast extract, 2% peptone, 2% glucose) with chloramphenicol (0.1 mg/L). Incubation was at 30°C for 5 days to allow colony formation. From count plates presenting between 30 and 300 colonies, 30 colonies were randomly selected. Selective lysine medium (Biolab, Merck), promoting the growth of yeasts other than S. cerevisiae, was used to ensure that no S. cerevisiae had been selected (Heard & Fleet, 1986). The selected colonies were purified and stored at 4°C until further analysis. Stock cultures were kept in glycerol at -80°C.

After commercial harvesting and processing of the grapes by the respective cellars, 500 mL samples of sedimented must were collected in sterile bottles. Isolation of the yeast then followed the same protocol as already described for the vineyard samples.

Characterisation of yeast isolates

The yeast isolates were characterised on the basis of biochemical profiles and pulse field gel electrophoresis.

Biochemical profiles

Biochemical profiles of each of the isolates were generated using the ID 32C AUX system (BioMérieux, France). Profiles were read after 48 h and the identity supplied by the database was used as a preliminary identity. If no identity could be assigned, a code number linked to the biochemical profile was given to the isolate.

Preparation of intact chromosomal DNA and pulse field gel electrophoresis

Samples were prepared according to the embedded agarose procedure of Carle & Olson (1985). Intact chromosomal DNA was separated using contour clamped homogenous electric field (CHEF) electrophoresis (CHEF-DR II, Bio-Rad Laboratories, Richmond, USA). All separations were carried out in 1% agarose gels (90 sec pulse for 15 h; 120 sec pulse for 20 h, in TBE buffer at 10°C). Gels were stained with ethidium bromide (10 mg/L), viewed on a trans-illuminator and then photographed.

A standard reference yeast (S. cerevisiae strain Vin 13, Anchor Bio-Technologies, South Africa) was used on each CHEF gel, as three gels were needed to characterise the 30 isolates per sampling point. The banding pattern of each yeast isolate was digitised and compared to the others using a customised computer program (CHEF vl.4 © T. Potgieter, ARC Infruitec-Nietvoorbij). This program allows DNA banding patterns to be digitised and stored in a database. Bands can then be compared to a specific pattern or all the patterns in the database.

Grouping and identification of isolates

The computer program, visual data (chromosomal banding patterns) and the biochemical profiles (identity or code number) were used to group yeasts. Identities supplied by the ID 32C system were noted. Subsequently, one representative yeast from each group was sent to a commercial laboratory (CBS, Delft, The Netherlands) for identification. That identification was then used as the identification for the other yeasts in the group.

Meteorological data

The monthly rainfall and average monthly maximum temperature (1996 to 2000) for the Constantia, Stellenbosch, Stanghoek and Robertson areas were obtained from Agromet (R. Wentzel, personal communication, 2001).

RESULTS AND DISCUSSION

Sample areas and climatic conditions

The four areas chosen for sampling represent four different climatic zones (Fig. 1). The Constantia area, the coolest, has a mean February temperature (MFT) (February being the harvest month)
of 19 to 21°C and is close to the Atlantic Ocean with its cooling sea breezes. The next area, Stellenbosch, is slightly warmer, with a MFT of 21 to 23°C, but also has an open aspect towards the sea. The Slanghoek area has a similar MFT to Stellenbosch, but lies behind a range of mountains that blocks most of the maritime influence. The last area, Robertson, is the furthest inland and is the warmest area, with a MFT of 23 to 25°C.

From heat summation data and rainfall figures, it is evident that the growing and pre-1997 harvest period (December 1996, January-February 1997) had more rain than usual, resulting in a cooler season (V. Bonnardot, personal communication, 2001). The pre-harvest period for 1998 showed less rainfall and was therefore warmer than normal. The pre-harvest period for 2000 was also warm and dry.

Sample collection and yeast isolation
Aseptic harvesting of the grapes and laboratory preparation of the must avoided contamination of samples by yeasts not present on the grapes. The must preparation technique used for the subsequent isolation of indigenous non-Saccharomyces yeasts from the vineyard samples was considered adequate for the same reasons as laid out by Van der Westhuizen et al. (2000a) and Bisson & Kunkee (1991). They argued that the more aggressive yeast recovery techniques, i.e. sonification of grapes as followed by Martini et al. (1980, 1996), while resulting in larger quantities of yeasts, did not lead to identification of any novel organisms, compared to milder sample preparation techniques. Our approach would furthermore clearly bias results towards yeast that would potentially have some oenological use.
The yeast characterisation and identification

The use of YPD agar plates incubated for five days ensured that slow-growing non-Saccharomyces yeasts could also grow, while the added antibiotic prevented any bacterial growth. The use of lysine media at this early stage could have suppressed slow-growing non-Saccharomyces yeasts, as well as S. cerevisiae. However, once the isolates had been selected, the non-Saccharomyces status was confirmed by the ability to grow on lysine medium and from electrophoretic karyotyping. Random selection of 30 colonies from the count plates (between 30 and 300 colonies) represents from 100% to only 10% of the possible isolates. While it is obvious that some minor species may have been overlooked on the plates with higher cell counts, the random selection ensured that predominant species were selected.

Yeast characterisation and identification

The use of the biochemical profiles and chromosomal banding patterns proved adequate for the grouping of similar species. However, the preliminary identification supplied by the ID 32 C database was often incorrect. This was to be expected, as the system was designed for the identification of yeasts of clinical importance. However, correct identifications were obtained for K. apiculata, Candida colliculosa, Candida pelliculosa, Candida guilliermondii, Candida albicans and Rhodotorula spp. While not in the database, C. stellata gave a consistent profile, which was correlated to the identification supplied by CBS.

The yeasts identified by CBS were, where applicable, found to be the anamorphic form. Although the teleomorphic form may have been isolated originally, the yeasts had been kept in storage for some time before identification. This can result in a loss of sporulation (Yarrow, 1998; M. Th. Smith, personal communication, 2000).

Non-Saccharomyces yeasts in vineyard samples

The four vineyards that were investigated over three vintages represent 12 sampling points (samples). While this study was not an exhaustive survey, and one vineyard cannot be extrapolated to the whole area, it does give us some indication of the type of population dynamics that occurred. Grape microflora are affected by factors such as temperature, rainfall, humidity, vineyard altitude, insect vectors, vineyard spray regimes, nitrogen fertilisation practices, winery waste practices and the health of the grapes (Boulton et al., 1996). It therefore should be expected that different regions will show differences in the proportion of yeasts (Amerine et al., 1967; Longo et al., 1991). Varietal factors, e.g. thickness of grape skins, can also play a role (Bisson & Kunkee, 1991). However, as only one cultivar was investigated, grape skin thickness can be disregarded in this investigation.

The total cell counts (Table 1) range from 1.6 x 10^6 to 1.2 x 10^8 cells/mL and - apart from a slight reduction in average cell counts in 1998 (by a factor of 10) - showed no apparent correlation to weather patterns or climate. However, prior to the 1997 harvest, there was a severe outbreak of fungal diseases in the vineyards due to the cooler weather and rainfall. To combat this, heavy applications of chemical sprays were applied during the growing season. In the 1998 vintage chemical sprays were used again due to the high fungal spore load from the previous season. This has been suggested as a possible cause for reduced yeast presence on grapes (Parish & Carroll, 1985; Van der Westhuizen et al., 2000a). However, preliminary work done by Sturm et al. (2002) showed that yeast species biodiversity was not influenced by pest and disease management practices (integrated pest management, organic farming, application of antagonistic bacteria and copper applications). In contrast, Cabras et al. (1999) showed that certain pesticides can stimulate yeasts such as K. apiculata.

The number of non-Saccharomyces species isolated in each sample ranged from one to four, with the exception of Stellenbosch, where eight species were isolated in 1997 (Table 2). There appears to be no pattern relating to weather and climatic conditions. In total, 15 species were isolated in this study. In a comparative study, regarding method of yeast isolation, Yanagida et al. (1992) isolated 12 species. Direct comparison with other studies is difficult as different approaches for yeast isolation were followed. In the previous South African investigation of 1961 (Van Zyl & Du Plessis, 1961) 15 species of non-Saccharomyces were also isolated. However, their approach entailed incubating berries in sterile grape juice until growth was observed. Studies in other parts of the world found between nine and 12 species (Parish & Carroll, 1985; Yanagida et al., 1992).

Single species predominance (>50% of isolates) occurred in 11 of the samples. No single species predominated in the twelfth sample. The species that had the highest incidence of predominance was K. apiculata, although in only five of the 12 samples. This scenario was also reported by Yanagida et al. (1992), who found K. apiculata predominance in only six of 11 sites. In the earlier study of South African vineyards (Van Zyl & Du Plessis, 1961), K. apiculata was listed as the most frequent; however, as already mentioned, their methodology would have played a role. Smaller numbers of K. apiculata were isolated in a further three samples in this study. However, it was absent in all three Robertson samples. In Constantia there appeared to be a tendency towards declining numbers of K. apiculata over the three vin-

Non-Saccharomyces yeasts in vineyards and must

Non-Saccharomyces yeasts are carried over to the must during crushing (Peynaud & Domercq, 1959; Bisson & Kunkee, 1991; Lonvaud-Funel, 1996). The specific must environment, i.e. low pH, high sugar content (high osmotic pressure), the presence of SO2 added at crushing and temperature, plays a role in determining which species of yeasts can survive and grow (Bisson & Kunkee, 1991; Longo et al., 1991). In addition, the method of harvesting (hand vs. mechanical), grape temperature, method and time of transport to cellar, time lapse before crushing, method of processing (whole bunches vs. crushing) and methods of clarification also play an important role in determining what yeast will be present in the clarified must (Fleet, 1990; Mora & Mulet, 1991; Epifanio et al., 1999; Pretorius 2000). From a winemaking point of view, it is important to know what non-Saccharomyces yeasts can survive and grow in must, as they are the ones that will have the most influence on wine quality.

In this study the vineyards were all commercial blocks with differing methods of harvest beyond the control of the authors. The Constantia, Stellenbosch and Robertson vineyards were harvested by hand, while the Slanghoek vineyard was machine harvested. These differences and the time taken to process the grapes can allow the yeast population to increase (Peynaud & Domercq, 1959). This makes actual comparisons between musts from the different cellars difficult.

The total number of cells in each must sample varied from $8.6 \times 10^3$ to $5.2 \times 10^6$ cells/mL (Table 3). On average the cell counts were higher in the cellar samples than in the vineyard samples. This increased cell number is due to the vineyard harvesting practices which can allow the yeast population to increase.

1. Dominant yeast (>50%) indicated in bold type.
may be due to the longer time that the yeasts were exposed to the nutrients in the must. It is also an indication that some of the non-
Saccharomyces yeasts are not as sensitive to SO2 as is generally assumed. The diversity of yeasts was very similar to the vineyard samples (three to eight species per sample) (Table 4). The exception was Robertson (1998), where only one group was isolated. This is comparable to other studies, where the total number of species isolated varied from two to 27 (Peynaud & Domercq. 1959; Fleet et al, 1984; Parish & Carroll, 1985; Mora & Mulet, 1991; Longo et al, 1991; Schütz & Gafner, 1993; Constanti et al, 1997).

Predominance by four yeast species was found in eight samples. They were C. stellata (four samples), K. apiculata (two samples), C. colliculosa (one sample) and C. pulcherrima (one sample). Another species found in high numbers was C. guilliermondii (43%) in Robertson 2000.

C. stellata (Constanti et al, 1997; Torija et al, 2001) and K. apiculata (Constanti et al, 1997) have previously been reported as predominant at the start of wine fermentation. However, Van Zyl & Du Plessis (1961) found low numbers of Kloeckera sp. during their investigation. They attributed this to the high levels of SO2 used to aid settling. Modern cellars tend to use less SO2, enabling a higher proportion of non-Saccharomyces yeasts to survive. C. colliculosa has also previously been reported as predominant in grape must (Heard & Fleet, 1985; Torija et al., 2001) but not C. pulcherrima (Bisson & Kunkee, 1991; Longo et al, 1991; Torija et al, 2001).

The isolation of Rhodotorula sp. (7%) in Stellenbosch (2000) is unusual and is not in accordance to its non-fermentative metabolism (Longo et al, 1991). However, Rhodotorula spp. grow very slowly on normal YPD agar and its presence may easily be overlooked due to the rapid growth of other yeasts. It would be expected that its numbers would decline very quickly once fermentation commenced, as this yeast is very sensitive to ethanol.

Non-Saccharomyces Yeasts in Vineyards and Must

General comparison of vineyard and cellar isolates

Geographic location and weather patterns, while obviously impacting on non-Saccharomyces populations, are difficult to correlate with specific patterns in yeast population. Furthermore, the cellular processes and environment play an important role in determining the non-Saccharomyces population in must. Variations did occur in species diversity and numbers, and a small number of non-Saccharomyces yeasts tended to dominate in vineyards and must, but not in all the samples studied.

Generally there was a greater diversity of yeasts in the processed must than from the vineyard samples (Tables 2 & 4). While in some instances the must population contained yeasts also found in the vineyard, this was not always the case (e.g. Robertson in 1997 and 1998). The broader diversity of yeasts in the must may be due to yeasts obtained from the production equipment during grape processing. The yeasts in the must may also have been on the surface of the grapes in very low numbers and therefore were not isolated. During the subsequent crushing and settling, they could have multiplied to such an extent that they could be detected. Other species found in the vineyard, but not in the must, may have been unable to survive in the higher osmotic pressure of the must or may have been sensitive to SO₂ added to the must.

As can be seen from the data presented, it would be unwise to predict the indigenous non-Saccharomyces yeast must population purely from a limited study of the grapes in the vineyard. Obvious factors, such as the method of harvest, transportation to the cellar and subsequent processing techniques, will all impact on the non-Saccharomyces population. Added to this is the indigenous cellar population and enrichment of yeasts during the sedimentation and pre-alcoholic fermentation phase. The non-Saccharomyces yeasts that are finally represented in the clarified must will therefore be those most tolerant to the existing conditions in the must and will be in the best position to continue their growth and have an oenological impact on wine fermentation. The predominant yeasts may be expected to have the most effect on the subsequent wine fermentation and resultant wine quality. K. apiculata can form high levels of volatile acidity; however, not all strains carry this trait and other metabolites can have a positive contribution (Romano et al, 1992; Romano & Suzzi, 1993). Glycerol production by C. stellata has already been employed for the improvement of the analytical quality of wine (Ciani & Ferraro, 1998; Ferraro et al., 2000), while C. pulcherrima is known to produce high amounts of esters (Bisson & Kunkee, 1991). Esters can make a positive contribution to young wines with few cultivar characteristics.

CONCLUSIONS

As part of the broader programme previously mentioned, this study was successful in isolating and preserving an oenologically biased range of non-Saccharomyces yeasts found in South African vineyards and musts. In total this collection represents 24 different species, comprised of 720 yeast isolates. Of these, nine species predominated in the various samples investigated. Furthermore, each sampling point had a different yeast population, but no pattern linking species to climatic zone was observed. Four of the predominant species, i.e. C. colliculosa, C. pulcherrima, C. stellata and K. apiculata, were found in the grape must.

These species could therefore be expected to have the biggest impact on wine quality and their contribution should receive further attention. In addition, the effect of different winemaking parameters on these yeasts should also be investigated so that conditions favouring their growth can be maintained.
